Planck early results. X. Statistical analysis of Sunyaev-Zeldovich scaling relations for X-ray galaxy clusters*

Introduction

Clusters of galaxies are filled with a hot, ionised, intra-cluster medium (ICM) visible both in the X-ray band via thermal bremsstrahlung and from its distortion of the cosmic microwave background (CMB) from inverse Compton scattering, i.e., the Sunyaev-Zeldovich effect (Sunyaev & Zeldovich 1970, 1972, hereafter). The SZ signal can be divided into a kinetic SZ and a thermal SZ effect, originating from bulk and thermal motions of ICM electrons, respectively. Since the kinetic SZ is a second-order effect, we only consider the thermal SZ effect. Because of the different scaling of SZ and X-ray fluxes with electron density and temperature, SZ and X-ray observations are highly complementary. The combination of information from these two types of observations is a powerful one for cosmological studies, as well as for improving our understanding of cluster properties.

All-sky data from the Planck survey and the Meta-Catalogue of X-ray detected Clusters of galaxies (MCXC) are combined to investigate the relationship between the thermal Sunyaev-Zeldovich (SZ) signal and X-ray luminosity. The sample comprises 1600 X-ray clusters with redshifts up to ~1 and spans a wide range in X-ray luminosity. The SZ signal is extracted for each object individually, and the statistical significance of the measurement is maximised by averaging the SZ signal in bins of X-ray luminosity, total mass, or redshift. The SZ signal is detected at very high significance in all X-ray clusters. These data are used to study the evolution of the scaling relations for X-ray galaxy clusters as well as to compare values predicted from X-ray studies. There is no evidence of any deficit in these two types of observations is a powerful one for cosmological studies, as well as for improving our understanding of cluster properties.

Keywords. galaxies: clusters: intracluster medium – X-rays: galaxies: clusters – cosmology: observations

1. Introduction

Clusters of galaxies are filled with a hot, ionised, intra-cluster medium (ICM) visible both in the X-ray band via thermal bremsstrahlung and from its distortion of the cosmic microwave background (CMB) from inverse Compton scattering, i.e., the Sunyaev-Zeldovich effect (Sunyaev & Zeldovich 1970, 1972, hereafter). The SZ signal can be divided into a kinetic SZ and a thermal SZ effect, originating from bulk and thermal motions of ICM electrons, respectively. Since the kinetic SZ is a second-order effect, we only consider the thermal SZ effect. Because of the different scaling of SZ and X-ray fluxes with electron density and temperature, SZ and X-ray observations are highly complementary. The combination of information from these two types of observations is a powerful one for cosmological studies, as well as for improving our understanding of cluster properties.

ABSTRACT

All-sky data from the Planck survey and the Meta-Catalogue of X-ray detected Clusters of galaxies (MCXC) are combined to investigate the relationship between the thermal Sunyaev-Zeldovich (SZ) signal and X-ray luminosity. The sample comprises 1600 X-ray clusters with redshifts up to ~1 and spans a wide range in X-ray luminosity. The SZ signal is extracted for each object individually, and the statistical significance of the measurement is maximised by averaging the SZ signal in bins of X-ray luminosity, total mass, or redshift. The SZ signal is detected at very high significance in all X-ray clusters. These data are used to study the evolution of the scaling relations for X-ray galaxy clusters as well as to compare values predicted from X-ray studies. There is no evidence of any deficit in these two types of observations is a powerful one for cosmological studies, as well as for improving our understanding of cluster properties.
physics (see Birkinshaw 1999, for a review). In this framework, it is paramount to investigate to what degree the ICM properties inferred from SZ and X-ray data agree.

Unfortunately, there is currently no consensus on whether predictions for the SZ signal based on ICM properties derived from X-ray observation agree with direct SZ observations, hampering our understanding of the involved physics. Lieu et al. (2006) find evidence of a weaker SZ signal in the 3-year WMAP data than expected from ROSAT observations for 31 X-ray clusters. Bielby & Shanks (2007) reach similar conclusions using the same WMAP data and ROSAT sample and the additional Chandra data for 38 clusters. Conversely, Afshordi et al. (2007) find good agreement between the strength of the SZ signal in WMAP 3-year data and the X-ray properties of their sample of 193 massive galaxy clusters. The last findings are supported further by the results of Atroio-Barandela et al. (2008), whose analysis is based on the same SZ data and a larger sample of 661 clusters. Diego & Partridge (2010) argue that a large contamination from point sources is needed to reconcile the SZ signal seen in the WMAP 5-year data with what is inferred from a large sample of ROSAT clusters. However, using the same SZ data and a slightly larger but similar sample of ROSAT clusters, Melin et al. (2011) find good agreement between SZ signal and expectations. The latter finding is confirmed by the work by Andersson et al. (2011), where high quality Chandra data for 15 South Pole Telescope clusters are used. Finally, the WMAP 7-year data analysis by Komatsu et al. (2011) argues for a deficit of SZ signal compared to expectations, especially at low masses.

Improved understanding of this issue is clearly desired, since it would provide invaluable knowledge about clusters of galaxies and aid in the interpretation and exploitation of SZ surveys such as the South Pole Telescope (SPT, Carlstrom et al. 2011) survey, the Atacama Cosmology Telescope (ACT, Fowler et al. 2007), and Planck1 (Tauber et al. 2010). Since August 2009 the Planck satellite has been surveying the whole sky in nine frequency bands with high sensitivity and a relatively high spatial resolution. Planck data thus offer the unique opportunity to fully explore this heavily debated issue. As part of a series of papers on Planck early results on clusters of galaxies (Planck Collaboration 2011a,d,e,g,h), we present a study of the relationship between X-ray luminosity and SZ signal in the direction of ~1600 objects from the MCXC X-ray clusters compilation (Piffaretti et al. 2011) and demonstrate that there is excellent agreement between SZ signal and expectations from the X-ray properties of clusters.

The paper is organised as follows. In Sect. 2 we briefly describe the Planck data used in the analysis and present the adopted X-ray sample. In Sect. 3 we present the baseline model used in the paper. The model description is rather comprehensive because the model is also adopted in the companion papers on Planck early results on clusters of galaxies (Planck Collaboration 2011d,e,f,h). Section 4 describes how the SZ signal is extracted from Planck frequency maps at the position of each MCXC cluster and how these are averaged in X-ray luminosity bins. Our results are presented in Sect. 5 and robustness tests are detailed in Sect. 6. Our findings are discussed and summarised in 7.

1 Planck (http://www.esa.int/Planck) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states (in particular the lead countries France and Italy), with contributions from NASA (USA) and telescope reflectors provided by a collaboration between ESA and a scientific consortium led and funded by Denmark.

When necessary we adopt a $\Lambda$CDM cosmology with $H_0 = 70$ km s$^{-1}$/Mpc, $\Omega_M = 0.3$ and $\Omega_\Lambda = 0.7$ throughout the paper. The quantity $E(z)$ is the ratio of the Hubble constant at redshift $z$ to its present value, $H_0$, i.e., $E(z) = \Omega_m(1+z)^3 + \Omega_\Lambda$.

The total cluster mass $M_{500}$ is defined as the mass within the radius $R_{500}$ within which the mean mass density is 500 times the critical density of the universe, $\rho_{\text{crit}}(z)$, at the cluster redshift: $M_{500} = \frac{4}{3}\pi\rho_{\text{crit}}(z)500 R_{500}^3$. We adopt an overdensity of 500 since $R_{500}$ encloses a substantial fraction of the total virialised mass of the system while being the largest radius probed in current X-ray observations of large samples of galaxy clusters.

The SZ signal is characterised by $Y_{500}$ defined as

$$D_A^L(z) Y_{500} = \int P_d V \, dV,$$

where $D_A(z)$ is the angular distance to a system at redshift $z$, $\sigma_T$ is the Thomson cross-section, $c$ the speed of light, $m_e$ the electron rest mass, $P = nk T_e$ the pressure, defined as the product of the electron number density and temperature and the integration is performed over the sphere of radius $R_{500}$. The quantity $Y_{500}$ is proportional to the apparent magnitude of the SZ signal and $D_A^2 Y_{500}$ is the spherically integrated Compton parameter, which, for simplicity, will be referred to as SZ signal or intrinsic SZ signal in the remainder of the paper. All quoted X-ray luminosities are cluster rest frame luminosities, converted to the [0.1–2.4] keV band.

2. Data

In the following subsections we present the Planck data and the X-ray cluster sample used in our analysis. In order to avoid contamination from galactic sources in the Planck data we exclude the galactic plane: $|b| \leq 14$ deg from the maps. In addition, we exclude clusters located less than 1.5x beam full width half maximum (FWHM) from point sources detected at more than 10σ in any of the single frequency Planck maps, because such sources can strongly affect SZ measurements.

2.1. SZ data set

Planck (Tauber et al. 2010; Planck Collaboration 2011a) is the third generation space mission to measure the anisotropy of the CMB. It observes the sky in nine frequency bands covering 30–857 GHz with high sensitivity and angular resolution from 31′ to 5′. The Low Frequency Instrument LFI; (Mandolesi et al. 2010; Bersanelli et al. 2010; Mennella et al. 2011) covers the 30, 44, and 70 GHz bands with amplifiers cooled to 20 K. The High Frequency Instrument (HFI; Lamarre et al. 2010; Planck HFI Core Team 2011a) covers the 100, 143, 217, 353, 545, and 857 GHz bands with bolometers cooled to 0.1 K. Polarisation is measured in all but the highest two bands (Leahy et al. 2010; Rosset et al. 2010). A combination of radiative cooling and three mechanical coolers produces the temperatures needed for the detectors and optics (Planck Collaboration 2011b). Two Data Processing Centers (DPCs) check and calibrate the data and make maps of the sky (Planck HFI Core Team 2011b; Zacchei et al. 2011). Planck’s sensitivity, angular resolution, and frequency coverage make it a powerful instrument for galactic and extragalactic astrophysics as well as cosmology. Early astrophysics results are given in Planck Collaboration (2011e–x).

In this paper, we use only the six temperature channel maps of HFI (100, 143, 217, 353, 545 and 857 GHz), corresponding to (slightly more than) the first sky survey of Planck. Details of how these maps are produced can be found in Planck HFI Core Team (2011b); Planck Collaboration (2011d). At this early stage of the Planck SZ analysis adding the LFI channel maps does
not bring significant improvements to our results. We use the full resolution maps at HEALPix
nside = 2048 (pixel size 1.72′) and we assume that beams are adequately described by symmetric Gaussians with FWHM as given in Table 1. Uncertainties in our results due to beam corrections, map calibrations and uncertainties in bandpasses are small, as shown in Sect. 6 below.

2.2. X-ray data set

The cluster sample adopted in our analysis, the MCXC (Meta-Catalogue of X-ray detected Clusters of Galaxies), is presented in detail in Piffaretti et al. (2011). The information provided by all publicly available ROSAT All Sky Survey-based (NORAS: Böhringer et al. 2000, REFLEX: Böhringer et al. 2004, BCS: Ebeling et al. 1998, 2000, SGP: Crudace et al. 2002, NEP: Henry et al. 2006, MACS: Ebeling et al. 2007, 2010, and CIZA: Ebeling et al. 2002; Kocevski et al. 2007) and serendipitous (160SD: Mullis et al. 2003, 400SD: Burenin et al. 2007, SHARC: Romer et al. 2000; Burke et al. 2003, WARPS: Perlman et al. 2002; Horner et al. 2008, and EMSS: Giola & Luppino 1994; Henry 2004) cluster catalogues was systematically homogenised and duplicate entries were carefully handled, yielding a large catalogue of approximately 1800 clusters. For each cluster the MCXC provides, among other quantities, coordinates, redshifts, and luminosities. The latter are central to the MCXC and to our analysis because luminosity is the only available mass proxy for such a large number of X-ray clusters. For this reason we will focus here on how the cluster rest frame luminosities provided by the MCXC are computed. Other quantities such as total mass and cluster size will be discussed in Sect. 3 below, because they are more model dependent.

In addition to being converted to the cosmology adopted in this paper and to the [0.1–2.4] keV band (the typical X-ray survey energy band), luminosities are converted to that for an overdensity of 500 (see below). This allows us to minimise the scatter originating from the fact that publicly available catalogues provide luminosity measurements within different apertures. Because cluster catalogues generally provide luminosities measured within some aperture or luminosities extrapolated up to large radii (total luminosities), the luminosities \( L_{500} \) provided by the MCXC were computed by converting the total luminosities to \( L_{500} \) using a constant factor or, when aperture luminosities are available, by performing an iterative computation based on the REXCESS mean gas density profile and \( L_{500} - M_{500} \) relation. The REXCESS \( L_{500} - M_{500} \) calibration is discussed in Sect. 3 below. While the comparison presented in Sect. 5.3 of Piffaretti et al. (2011) indicates that the differences between these two methods do not introduce any systematic bias, it is clear that the iteratively computed \( L_{500} \) are the most accurate. The iterative computation was possible for the NORAS/REFLEX, BCS, SHARC, and NEP catalogues. As shown in Piffaretti et al. (2011) the luminosities \( L_{500} \) depend very weakly on the assumed \( L_{500} - M_{500} \) relation. Nevertheless, when exploring the different \( L_{500} - M_{500} \) relations detailed below, we consistently recompute \( L_{500} \) using the relevant \( L_{500} - M_{500} \) relation.

In addition, we supplement the MCXC sample with \( z \geq 0.6 \) cluster data in order to enlarge the redshift leverage. These additional high redshift clusters are collected from the literature by utilizing the X-Rays Clusters Database BAX\(^3\) and performing a thorough search in the literature. For these objects we collect coordinates, redshift, and X-ray luminosity. The luminosity values given in the literature are converted to the [0.1–2.4] keV band and adopted cosmology as done in Piffaretti et al. (2011). Because the available luminosities are derived under fairly different assumptions (e.g., aperture radius, extrapolation methods, etc.) we do not attempt to homogenise them to the fiducial luminosity \( L_{500} \) as done in Piffaretti et al. (2011). In almost all the cases the adopted luminosity is however either the total luminosity (i.e. extrapolated to large radii) or the directly the luminosity \( L_{500} \). Given the fact that the difference between these is close to 10% and that uncertainties affecting luminosity measurement of high redshift clusters are much larger, we treat all luminosities as fiducial luminosity \( L_{500} \).

The MCXC and \( z \geq 0.6 \) supplementary clusters located around the galactic plane (\( |b| \leq 14 \) deg) or near bright point sources (\( >10\sigma \), distance \( <1.5 \times \text{FWHM} \)) are excluded from the analysis. The resulting sample comprises 1603 clusters, with 845 clusters being members of the NORAS/REFLEX sample. There is a total of 33 supplementary \( z \geq 0.6 \) clusters located in the sky region selected in our analysis. In Fig. 1 we show luminosity and mass as a function of redshift for the whole sample with the NORAS/REFLEX and supplementary \( z \geq 0.6 \) clusters displayed with different colours. The figure shows the different clustering in the \( L - z \) plane of RASS (mostly NORAS/REFLEX) and serendipitously discovered clusters. The NORAS/REFLEX clusters are central to our study for many reasons. First, being the most luminous and numerous, they are expected to yield the bulk of the SZ signal from known clusters. Second, their distribution in the sky is uniform: NORAS and REFLEX cover the northern and southern sky, respectively, with the galactic plane excluded (\( |b| \leq 20 \) deg). Finally, the NORAS/REFLEX sample was also used in Melin et al. (2011) in an analysis equivalent to the one presented in this work but based on WMAP-5 yr data. For these reasons we use NORAS/REFLEX clusters as control sample in our analysis.

For simplicity, in the remainder of the paper the whole compilation of MCXC plus supplementary \( z \geq 0.6 \) clusters will be referred to as MCXC. The [0.1–2.4] keV luminosities of the clusters in our sample range from \( 1.53 \times 10^{40} \) to \( 2.91 \times 10^{45} \) erg s\(^{-1} \), with a median luminosity of \( 0.95 \times 10^{44} \) erg s\(^{-1} \) and redshifts range from 0.0031 to 1.45. Notice that while the adopted sample essentially comprises all known X-ray clusters in the sky region of interest, its selection function is unknown. The latter issue and how we evaluate its impact on our results is discussed in Sect. 3.1 below.

REXCESS clusters can be traced by XMM-Newton up to large cluster-centric distances, allowing robust measurements at an overdensity of 500. Since X-ray luminosity is the only available mass proxy for our large cluster sample, the most fundamental ingredient of the cluster model is the scaling relation between [0.1–2.4] keV band luminosity and total cluster mass, which is detailed in Sect. 3.1. Given a cluster redshift \( z \), mass \( M_{500} \) and hence cluster size \( R_{500} \), the universal pressure profile of Arnaud et al. (2010) is then used to predict the electronic pressure profile. This allows us to predict \( D_X^2 Y_{500} \), the SZ signal integrated in a sphere of radius \( R_{500} \) as summarised in Sect. 3.2. It is important to notice that the estimated cluster size \( R_{500} \) and the universal pressure profile are also assumed when extracting the SZ signal from Planck data as detailed in Sect. 4 below.

In the following we describe the assumptions at the basis of our fiducial model and provide the adopted scaling laws. In addition, we also discuss how these assumptions are varied in order to investigate the robustness of our results.

### 3.1. \( L_{500} - M_{500} \) relation

For a given [0.1–2.4] keV band luminosity \( L_{500} \) the total mass \( M_{500} \) is estimated adopting the REXCESS \( L_{500} - M_{500} \) relation (Pratt et al. 2009):

\[
E(z)^{-7/3} \left( \frac{L_{500}}{10^{44} \text{erg s}^{-1}} \right) = C_{\text{LM}} \left( \frac{M_{500}}{3 \times 10^{14} M_\odot} \right)^{\alpha_{\text{LM}}}. \tag{1}
\]

Because this relation has been calibrated using the low scatter X-ray mass proxy \( Y_X \) (Kravtsov et al. 2006), the parameters \( C_{\text{LM}} \) and \( \alpha_{\text{LM}} \) depend on whether the slope of the underlying \( M_{500} - Y_X \) relation is assumed to be equal to the standard (self-similar) value of \( \alpha_{\text{MYX}} = 3/5 \) or it is allowed to be a free parameter, yielding \( \alpha_{\text{MYX}} = 0.561 \) (see Eqs. (2) and (3) in Arnaud et al. 2010). In the reminder of the paper these two cases will be referred to as standard and empirical, respectively. Our fiducial model adopts the empirical case, which reflects the observed mass dependence of the gas mass fraction in galaxy clusters. It is thus fully observationally motivated.

In addition to these two variations of the \( L_{500} - M_{500} \) relation, we also consider the impact of Malmquist bias on our analysis.

### 3.2. The SZ signal

As shown in Arnaud et al. (2010), if standard evolution is assumed, the average physical pressure profile of clusters can be described by

\[
P(r) = P_0 \left( \frac{M_{500}}{3 \times 10^{14} M_\odot} \right)^{\alpha_p} \left( \frac{r}{R_{500}} \right)^{\alpha_p} \frac{P_0}{(c_{500} X)^{\alpha_p}(1 + (c_{500} X)^{\gamma})}, \tag{2}
\]

with \( x = r/R_{500} \) and \( \alpha_p = 1/\alpha_{\text{MYX}} - 5/3 \). In the standard case we have \( \alpha_p = 0 \), while in the empirical case \( \alpha_p = 0.12 \). Notice that the most precised empirical description also takes into account a weak radial dependence of the exponent \( \alpha_p \) of the form \( \alpha_p = 0.12 + \alpha_p(x) \). Here we neglect the radially dependend term since, as shown by Arnaud et al. (2010), it introduces a fully negligible correction.

To this end we perform our analysis using the \( L - M \) calibrations derived from REXCESS luminosity data corrected or uncorrected for the Malmquist bias. In the reminder of the paper these two cases will be referred to as the intrinsic and REXCESS \( L_{500} - M_{500} \) relations, respectively. Notice that the difference between the intrinsic and REXCESS \( L_{500} - M_{500} \) relations is very small at high luminosity (Pratt et al. 2009). Ideally, one should use the intrinsic \( L_{500} - M_{500} \) relation and compute, for each sample used to construct the MCXC compilation, the observed \( L_{500} - M_{500} \) relation according to each survey selection function. Unfortunately this would be possible only for a small fraction of MCXC clusters because the individual selection functions of the samples used to construct it are extremely complex and, in most of the cases, not known or not available. Therefore we simply consider the intrinsic \( L_{500} - M_{500} \) relation as an extreme and illustrative case, since it is equivalent to assuming that selection effects of our X-ray sample are totally negligible. On the other hand, in particular for the NORAS/REFLEX control sample and at high luminosities, the REXCESS \( L_{500} - M_{500} \) relation is expected to be quite close to the one that would be observed in our sample. For these reasons, our fiducial model adopts the REXCESS \( L_{500} - M_{500} \) relation and the intrinsic case is used to test the robustness of our results.

These different choices result in four different calibrations of the \( L_{500} - M_{500} \) relation. The corresponding best fitting parameters are summarised in Table 2 (see also Arnaud et al. 2010). Values are given for the fiducial case where the observed REXCESS \( L_X - Y_X \) and \( M - Y_X \) are assumed as well as for the cases where these two assumptions are varied: i.e. intrinsic (Malmquist bias corrected) \( L_X - Y_X \) relation and standard slope of the \( M - Y_X \) relation \( \alpha_{\text{MYX}} \). The table also lists the intrinsic dispersion in each relation, which we use to investigate the effect of scatter in the assumed mass-observable relation in our analysis.

For a given \( L_{500} - M_{500} \) relation we estimate, for each cluster in our sample, the total mass \( M_{500} \) from its luminosity \( L_{500} \). When the latter is computed iteratively (see Sect. 2.2), the same \( L_{500} - M_{500} \) relation is adopted for consistency. Finally, the cluster size or characteristic radius \( R_{500} \) is computed from its definition: \( M_{500} = \frac{4}{3} \pi \rho_{\text{crit}}(z) 500 R_{500}^3 \).

The characteristic pressure \(P_{500}\) is defined as

\[
P_{500} = 1.65 \times 10^{-3} E(z)^{2/3} \left( \frac{M_{500}}{3 \times 10^{14} M_\odot} \right)^{2/3} \text{keV cm}^{-3}.
\]

The set of parameters \([P_0, c_{500}, \gamma, \alpha, \beta]\) in Eq. (2) are constrained by fitting the \textsc{rexcess} data and depend on the assumed slope of the \(M - Y_X\) relation. In Table 3 we list the adopted best-fitting values, which, as detailed in Sect. 4, below, are also used to optimise the SZ signal detection. Values are first given for the fiducial case where the observed \(M - Y_X\) relation (with slope \(a_{\text{MYX}} = 0.561\)) and the average profile of all \textsc{rexcess} clusters are adopted. The values for the average core-cool (CC) and morphologically disturbed (MD) \textsc{rexcess} profiles, that we use to estimate the uncertainties originating from deviations from the average profile (see Sect. 6), and the average profile derived assuming a standard slope of the \(M - Y_X\) relation (\(a_{\text{MYX}} = 3/5\)), are also listed in the table.

Because of the large number of free parameters, there is a strong parameter degeneracy and therefore a comparison of individual parameters in Table 3 is meaningless. The parameters for the standard case are also listed in the table.

The model allows us to compute the physical pressure profile as a function of mass \(M_{500}\) and \(z\) and thus to obtain the \(D_A(z)\) for each cluster individually by cutting from each of the six \textsc{hfi} frequency maps 10° × 10° patches (pixel = 1.72 arcmin) centred at the cluster position. The resulting set of six \textsc{hfi} frequency patches is then used to extract the cluster signal by means of multifrequency matched filters (MMF, hereafter). The main features of the multifrequency matched filters are summarised in Melin et al. (2011) and more details can be found in Herranz et al. (2002) and Melin et al. (2006).

The MF method optimally filters and combines the patches to estimate the SZ signal. It relies on an estimate of the noise auto- and cross-power-spectra from the patches. Working with sky patches centred at cluster positions allows us to get the best estimates of the local noise properties. The MMF also makes assumptions about the spatial and spectral characteristics of the cluster signal and the instrument. Our cluster model is described below, for the instrumental response we assumed symmetric Gaussian beams with FWHM given in Table 1.

We determine a single quantity for each cluster from the \textit{Planck} data, the normalisation of an assumed profile. All the parameters determining the profile location, shape and size are fixed using X-ray data. We use the profile shape described in Sect. 3 with \(c_{500}\), \(\alpha\), \(\beta\) and \(y\) fixed to the values given in Table 3 and integrate along the line-of-sight to obtain a template for the cluster SZ signal. The integral is performed by considering a cylindrical volume and a cluster extent of 5 × \(R_{500}\) along the line-of-sight. The exact choice of the latter is not relevant. The normalisation of the profile is fitted using data within a circular aperture of radius 5 × \(R_{500}\) for each system in our X-ray cluster catalogue, centring the filter on the X-ray position and fixing the cluster size to \(\theta_{500} = R_{500}/D_A(z)\). Notice that the dependence of cluster size on X-ray luminosity is weak (\(R_{500} \propto L_{500}^{0.2}\) from Eq. (1)), implying that MMF measurements are expected to be relatively insensitive to the details of the underlying \(L_{500} - M_{500}\) relation.

The MMF method yields statistical SZ measurement errors \(\sigma_i\) on individual measurements. The statistical error includes uncertainties due to the instrument (beam, noise) and to the astrophysical contaminants (primary CMB, Galaxy, point sources). Obviously, it does not take into account the uncertainties on our X-ray priors and instrumental properties which will be studied in Sect. 6.

The same extraction method is used in \textit{Planck} Collaboration (2011h) where the optical-SZ scaling relation with MaxBCG clusters (Koester et al. 2007) are investigated. There are only two differences. First, in this paper we use the X-ray with the observed SZ signal, whose measurement is detailed in the next section.

To reiterate, our fiducial case assumes: empirical slope of \(M - Y_X\) relation and \textsc{rexcess} \(L_{500} - M_{500}\) relation. If not otherwise stated, in the remainder of the paper results for the fiducial case are presented and results obtained by varying the assumptions are going to be compared to it in Sect. 6.

For simplicity the cluster size and SZ signal for the MCXC clusters in \textit{Planck} Collaboration (2011d) are provided in the standard \(M_{500} - Y_X\) slope case. As we show in \textit{Planck} Collaboration (2011d) the effects of this on X-ray size and both predicted and observed SZ quantities for clusters in the Early Sunyaev-Zeldovich (ESZ) catalog are fully negligible with respect to the overall uncertainties.

4. Extraction of the SZ signal

4.1. Individual measurements

The SZ signal is extracted for each cluster individually by cutting from each of the six \textsc{hfi} frequency maps 10° × 10° patches (pixel = 1.72 arcmin) centred at the cluster position. The resulting set of six \textsc{hfi} frequency patches is then used to extract the cluster signal by means of multifrequency matched filters (MMF, hereafter). The main features of the multifrequency matched filters are summarised in Melin et al. (2011) and more details can be found in Herranz et al. (2002) and Melin et al. (2006).

The MMF algorithm optimally filters and combines the patches to estimate the SZ signal. It relies on an estimate of the noise auto- and cross-power-spectra from the patches. Working with sky patches centred at cluster positions allows us to get the best estimates of the local noise properties. The MMF also makes assumptions about the spatial and spectral characteristics of the cluster signal and the instrument. Our cluster model is described below, for the instrumental response we assumed symmetric Gaussian beams with FWHM given in Table 1.

We determine a single quantity for each cluster from the \textit{Planck} data, the normalisation of an assumed profile. All the parameters determining the profile location, shape and size are fixed using X-ray data. We use the profile shape described in Sect. 3 with \(c_{500}\), \(\alpha\), \(\beta\) and \(y\) fixed to the values given in Table 3 and integrate along the line-of-sight to obtain a template for the cluster SZ signal. The integral is performed by considering a cylindrical volume and a cluster extent of 5 × \(R_{500}\) along the line-of-sight. The exact choice of the latter is not relevant. The normalisation of the profile is fitted using data within a circular aperture of radius 5 × \(R_{500}\) for each system in our X-ray cluster catalogue, centring the filter on the X-ray position and fixing the cluster size to \(\theta_{500} = R_{500}/D_A(z)\). Notice that the dependence of cluster size on X-ray luminosity is weak (\(R_{500} \propto L_{500}^{0.2}\) from Eq. (1)), implying that MMF measurements are expected to be relatively insensitive to the details of the underlying \(L_{500} - M_{500}\) relation.

The MMF method yields statistical SZ measurement errors \(\sigma_i\) on individual measurements. The statistical error includes uncertainties due to the instrument (beam, noise) and to the astrophysical contaminants (primary CMB, Galaxy, point sources). Obviously, it does not take into account the uncertainties on our X-ray priors and instrumental properties which will be studied in Sect. 6.

The same extraction method is used in \textit{Planck} Collaboration (2011h) where the optical-SZ scaling relation with MaxBCG clusters (Koester et al. 2007) are investigated. There are only two differences. First, in this paper we use the X-ray
scaling $L_{500} - M_{500}$ to adapt our filters to the sizes of our clusters while we use the optical $N_{500} - M_{500}$ relation of Johnston et al. (2007) and Rozo et al. (2009) in the other paper. Second, the MaxBCG catalogue includes ~14,000 clusters so we do not build a set of patches for each cluster individually. Instead, we divide the sphere into 504 overlapping patches ($10^\circ \times 10^\circ$, pixel = 1.72 arcmin) as in Melin et al. (2011). We also extract SZ signal for each cluster individually but the clusters are no longer located at the centre of the patch.

Under the assumption that the shape of the adopted profile template corresponds to the true SZ signal, our extraction method allows us to convert the signal in a cylinder of aperture radius $5 \times R_{500}$ to $Y_{500}$, the SZ signal in a sphere of radius $R_{500}$. By definition the conversion factor is a constant factor for every cluster but depends on the assumed profile. The effect of the uncertainties on the assumed profile are discussed in Sect. 6 below.

The intrinsic SZ signal is computed by taking into account the angular distance dependence of the observed signal and is expressed as $(D_A(z)/500\,\text{Mpc})^2 Y_{500}$. This signal has units of arcmin$^{-2}$ as for the observed quantity, but its value differs from the intrinsic signal in units of Mpc$^{-2}$ by a constant, redshift-independent factor. Making such a conversion allows us to directly compare our measurements with the predictions derived from the model detailed in Sect. 3 (see in particular Eqs. (4) and (5)). When a specific scaling relation is investigated, the SZ signal is appropriately scaled according to the adopted scaling relations presented in Sect. 3 (e.g., see the left-hand panel of Fig. 2).

The SZ signal for all the clusters in our sample is shown as a function of the $[0.1–2.4]$ keV band X-ray luminosity in the left-hand panel of Fig. 2. Assuming standard evolution the intrinsic quantities $(D_A(z)/500\,\text{Mpc})^2 Y_{500}$ are plotted as a function of $L_{500} E(z)^{-7/4}$. The figure shows that Planck detects the SZ signal at high significance for a large fraction of the clusters.

### 4.2. Binned SZ signal

As shown in the left-hand panel of Fig. 2 the SZ signal is not measured at high significance for all of the clusters. In particular, low luminosity objects are barely detected individually. We therefore take advantage of the large size of our sample and average SZ measurements in X-ray luminosity, mass, or redshift bins. The bin average of the intrinsic SZ signal is defined as the weighted mean of the signal in the bin (with inverse variance weight, $\sigma_i^{-2}$, scaled to the appropriate redshift or mass dependence depending on the studied scaling relation) and the associated statistical errors are computed accordingly. The binning depends on the adopted relation and will be detailed in each case.

In the left-hand panel of Fig. 2 the binned signal is overlaid on the individual measurements. In this case the SZ signal is averaged in logarithmically spaced luminosity bins. We merged the lowest four luminosity bins into a single bin to obtain a significant result. The statistical uncertainties, which are depicted by the thick error bars, are not visible in the figure and clearly underestimate the uncertainty on the binned values.

A better estimate of the uncertainties in the binned values comes from an ensemble of 10,000 bootstrap realisations of the entire X-ray cluster catalogue. Each realisation is constructed from the original data set by random sampling with replacement, where all quantities of a given cluster are replaced by those of another cluster. Each realisation is analysed in the same way as the original catalogue and the standard deviation of the average signal in each bin is adopted as total error. Bootstrap uncertainties, which take into account both sampling and statistical uncertainties, are shown by the thin error bars in the left-hand panel of Fig. 2. A visual inspection of the figure indicates that the SZ signal is detected at high significance over a wide luminosity range. The lack of clear detection at $L_{500} E(z)^{-7/4} \lesssim 0.05 \times 10^{44}$ erg s$^{-1}$ is due to the combined effect of low signal and small number of objects. In the companion paper Planck Collaboration (2011h) we explore this low luminosity (mass) range in more depth. The results of these two complementary analysis are summarised and discussed in Sect. 7 (see Fig. 10 and related discussion).

The difference between statistical and bootstrap errors are rendered in more detail in Fig. 3, where relative bootstrap uncertainties (dot-dashed line) are compared to in-bin relative statistical errors (solid line). The figure shows that for
Fig. 3. Bin averaged relative statistical errors (solid line) and relative bootstrap errors (dot-dashed line) are shown as a function of X-ray luminosity. The numbers given in the legend indicate the number of objects in each luminosity bin. For comparison, the scaled unweighted standard deviation (dashed line) is also shown.

$L_{500} E(z)^{-7/3} \lesssim 10^{44}$ erg s$^{-1}$ statistical uncertainties are dominant. This implies that intrinsic scatter, which is discussed in more detail in Sect. 5.3, can only be measured at higher luminosity.

Figure 3 also shows the quantity $(1/\sqrt{N}) \times (\sigma_{\text{raw}} / Y)$ (dashed line), which is computed from the unweighted raw scatter $\sigma_{\text{raw}}$, the bin average $Y$, and the number of clusters in the bin $N$. The difference between the latter and the relative bootstrap uncertainties in the low luminosity bins is due to the range of relative errors on individual measurements in a given bin.

As a robustness check, we have undertaken the analysis a second time using random cluster positions but keeping all the properties of our sample (sizes, profile shape). The result is shown by the green triangles in the right-hand panel of Fig. 2 and, as expected, is consistent with no detection of the SZ signal. This demonstrative null test clearly shows the efficiency of the MMF to pull out the SZ signal from our cluster sample. Additional robustness test are discussed in Sect. 6 below.

5. Results

5.1. The $D^2_{A,Y} Y_{500} - L_{500}$ and $D^2_{A,Y} Y_{500} - M_{500}$ relations

The main results of our analysis are summarised in Fig. 4. In the left-hand panel of the figure the individual and luminosity binned Planck SZ signal measured at the location of MCXC clusters are shown as a function of luminosity together with the luminosity averaged model predictions. The latter are computed by averaging the model prediction for individual clusters (see Sect. 3) with the same weights as for the measured signal. Notice that SZ signal and X-ray luminosity are intrinsic quantities and are scaled assuming standard evolution. The figure shows the high significance of the SZ signal detection and the excellent agreement between measurements and model predictions. The agreement between Planck measurements and X-ray based predictions is rendered in more detail in the right-hand panel of Fig. 4 where the Planck-to-model ratio is plotted. Taking into account the total errors given by the bootstrap uncertainties (thin bars in the figure), the agreement is excellent over a wide luminosity range. We model the observed $D^2_{A,Y} Y_{500} - L_{500}$ relation shown in the left-hand panel of Fig. 4 by adopting a power law of the form

$$Y_{500} = \tilde{Y}_{500,L} \left(\frac{E(z)^{-7/3} L_{500}}{10^{44} \text{ erg s}^{-1}}\right)^{\tilde{\beta}_L} E(z)^{\tilde{\beta}_E} \left(\frac{D_A(z)}{500 \text{ Mpc}}\right)^{-2}$$

and directly fitting the individual points shown in the figure rather than the binned data points. We use a non-linear least-squares fit built on a gradient-expansion algorithm (the IDL curvefit function). In the fitting procedure, only the statistical errors given by the MMF are taken into account. The derived uncertainties on the best fitting parameters are quoted in Table 4 as statistical errors. In addition, uncertainties on the best fitting parameters are estimated through the bootstrap procedure described in Sect. 4. Each bootstrap catalogue fit leads to a set of parameters whose standard deviation is quoted as the uncertainty on the best fitting parameters. Values are given for three different choices of priors as given in Table 4, where the best fitting parameters are listed. The table also provides the prediction of our X-ray based model for comparison.

Figures 5 shows the measured and predicted $D^2_{A,Y} Y_{500} - M_{500}$ relation, the best fitting amplitude is $0.451 \times 10^{-3}$ arcmin$^{-2}$ in agreement with the model prediction $0.428 \times 10^{-3}$ arcmin$^{-2}$ at 1.8$\sigma$. When keeping the redshift dependence of the relation fixed but leaving the slope of the relation free, we find agreement between best fitting and predicted slopes at better than 1$\sigma$, while the amplitudes remain in agreement at 1.3$\sigma$. For maximum usefulness and in particular to facilitate precise comparisons with our findings, we provide, in Table 5, the data points shown in the left-hand panel of Fig. 4. Values are given for the quantities $L_{500} = L_{500}(E(z)^{-7/3})$ in units of $10^{44}$ erg s$^{-1}$ and $\tilde{Y}_{500} = Y_{500}(E(z)^{-2/3}/D_A(z)/500 \text{ Mpc})^2$ in units of $10^{-3}$ arcmin$^{-2}$. Both total (i.e., bootstrap) and statistical errors on $\tilde{Y}_{500}$ are also listed.

For completeness, we also investigate the $D^2_{A,Y} Y_{500} - M_{500}$ relation, where the masses $M_{500}$ are computed from the $L_{500}$ - $M_{500}$ relation given in Eq. (1). Following the same procedure as for the $D^2_{A,Y} Y_{500} - L_{500}$ relation, we fit individual points of the $D^2_{A,Y} Y_{500} - M_{500}$ plane with

$$Y_{500} = \tilde{Y}_{500,M} \left(\frac{M_{500}}{3 \times 10^{14} M_\odot}\right)^{\tilde{\beta}_M} E(z)^{\tilde{\beta}_E} \left(\frac{D_A(z)}{500 \text{ Mpc}}\right)^{-2}.$$  

The same cases as for the $D^2_{A,Y} Y_{500} - L_{500}$ relation are considered and the best fitting parameters are provided in Table 6 along with the model prediction. Concerning the agreement between best fitting parameters and model predictions, the conclusions drawn for the $D^2_{A,Y} Y_{500} - L_{500}$ relation obviously apply also for the $D^2_{A,Y} Y_{500} - M_{500}$.

5.2. Redshift evolution

We also considered the case where the redshift evolution of the scaling relations is allowed to differ from the standard expectation. Using the simplest model (Eq. (7) or equivalently Eq. (8)) we attempt to constrain the power law index $\tilde{\beta}_E$ (or equivalently $\tilde{\beta}_M$). We find that the measured SZ signal is consistent with standard evolution (see Table 4) and our constraints on any evolution are weak. Figure 5 shows the measured and predicted, redshift binned, SZ signal, the expected standard redshift evolution, and the best fitting model. The figure shows that, although measurements and predictions agree quite well, the best fitting model is constrained primarily by the low redshift measurements. Possible future improvements are discussed below in Sect. 7.
of the adopted \( D_\lambda^2 \) and \( L_{500} \) relations (Eq. (6)) is shown by the dashed blue line while the red dot-dashed line shows the best fitting power-law to the data (Eq. (7) and Table 4).

5.3. Scatter in the \( D_\lambda^2 \) \( \sim \) \( L_{500} \) relation

As discussed in Sect. 4.2, we find a clear indication of intrinsic scatter in our measurements of the \( D_\lambda^2 \) \( \sim \) \( L_{500} \) relation. In this section we quantify this scatter and discuss how our measurement compares with expectations based on the representative REXCESS sample (Arnaud et al. 2010) and the findings reported in the companion paper discussing high quality observations of local clusters (Planck Collaboration 2011g).

The intrinsic scatter \( \sigma_{\text{intr}} \) is computed in luminosity bins as the quadratic difference between the raw scatter \( \sigma_{\text{raw}} \) (see Sect. 4.2) and the statistical uncertainty expected from the raw scatter (see Sect. 4.2). In a given bin with average signal \( Y \), the resulting fractional intrinsic scatter \( \sigma_{\text{intr}} / Y \) is shown in Fig. 6 along with the fractional raw and statistical scatters. The estimated intrinsic scatter is close to 40–50% and in agreement with the expectations given in Arnaud et al. (2010) (\( \sigma_{\text{log} Y_{\text{raw}}} = 0.184 \pm 0.024 \), the range of these values is indicated by the coarse–hatched region in the figure). Notice that the intrinsic scatter reported in Arnaud et al. (2010) is computed for the REXCESS sample and evaluated adopting XMM-Newton luminosities and a predicted SZ signal for individual objects based on the model assumed here but relying on the mass proxy \( Y \). Therefore, the intrinsic scatter quoted in Arnaud et al. (2010) reflects the intrinsic scatter in the underlying \( L_{500} \) \( \sim \) \( M_{500} \) relation. In Planck Collaboration (2011g), where a sample of clusters detected at high signal to noise in the Planck survey (the ESZ sample, see Planck Collaboration 2011d) and with high quality X-ray data from XMM-Newton is used, the intrinsic scatter in the \( D_\lambda^2 \) \( \sim \) \( L_{500} \) relation is found to be \( \sigma_{\text{log} Y_{\text{raw}}} = 0.143 \pm 0.016 \). These
values are shown in Fig. 6 by the fine–hatched region. In Planck Collaboration (2011g) it is found that cool core clusters are responsible for the vast majority of the scatter around the relation. Because the sample used in this study is X-ray selected, we expect it to contain a higher fraction of cool core systems than in the ESZ subsample studied in Planck Collaboration (2011g). This implies that the scatter in the $D_A^2 Y_{500} - L_{500}$ relation measured in our sample is expected to be higher than the one found in Planck Collaboration (2011g), as observed. Given the segregation of cool core systems in the $D_A^2 Y_{500} - L_{500}$ reported in Planck Collaboration (2011g), we investigate the link between the intrinsic scatter in the relation and cluster dynamical state using our large X-ray sample. To this end we compare Planck measurements and the X-ray based predictions (i.e., Eq. (6)) for individual objects. In Fig. 7 we show the difference between Planck measurement and the X-ray based prediction in units of the measurement statistical error $\sigma_i$ (see Sect. 4) as a function of X-ray luminosity and investigate the largest outliers the figure, i.e. the most statistically significant outliers in the $D_A^2 Y_{500} - L_{500}$ relation.

Given the size of our sample we discuss individually only clusters for which measurement and prediction differ by more than $5\sigma_i$. These are identified and information on their dynamical state is searched for in the literature. Information is based on the classification of Hudson et al. (2010) if not stated otherwise. We find 15 clusters with a predicted signal smaller than the Planck measurement by more than $5\sigma_i$. Of these, six are known merging clusters: Coma, A2218 (Govoni et al. 2004), 1ES0657, A754 (Govoni et al. 2004), A2163 (Bourdin et al. 2011), A0697 (Girardi et al. 2006), six are classified as non-cool core clusters and may therefore be unrelaxed: A2219 (Allen & Fabian 1998), A2256, A2255, A0209 (Zhang et al. 2008), A2813 (Zhang et al. 2008), A3404 (Pratt et al. 2009), and A3266 is a weak cool core cluster. No information is available for the remaining clusters: A1132 and A3186. Conversely, there are 11 over-predicted clusters at $5\sigma_i$. Of these five are strong cool core clusters: 2A0335, Zw1021.0+0426 (Morandi et al. 2007), A3112, HerA (Bauer et al. 2005), and A0780. No information is available for the remaining clusters: A689, ACOS1111, A3392, J1253.6-3931, J1958.2-3011, and RXCJ0643.4+4214. Notice that the luminosity of A689 is likely to be overestimated by a large factor because of point source contamination (Maughan 2008). In addition, for A3186 and ACOS1111 the model prediction rely on the EMSS luminosity measurements given in Gioia & Luppino (1994), which might be unreliable.

The high fraction of dynamically perturbed / cool-core clusters with largely under/over predicted SZ signal is confirmed when additional outliers at smaller $\sigma_i$ are searched. We find 65 clusters with ($Y_{500}$ Planck – $Y_{500}$ Model) $> 3\sigma_i$ and that for 46 percent of them dynamical state information is available in the literature. Of the latter 26 (87 percent) are either known mergers or non-cool core clusters, two are weak cool core clusters, and only one is classified as cool core cluster. We find 53 clusters with ($Y_{500}$ Planck – $Y_{500}$ Model) $< -3\sigma_i$. For 45 percent of these clusters we are able to find information on their dynamical state.

**Fig. 5.** Bin averaged SZ signal from a sphere of radius $R_{500}$ ($Y_{500}$) scaled by the expected standard redshift evolution (dashed line). The best fitting values are shown in Fig. 6 by the fine–hatched region. The coarse/fine-hatched regions corresponds to the 1 $\sigma$ uncertainties on the intrinsic scatter reported in Arnaud et al. (2010) and Planck Collaboration (2011g), respectively.

**Fig. 6.** Fractional raw (dot-dashed blue line and triangles), statistical (dot-dashed green line and plus signs), and intrinsic (dashed red line, diamonds, and error bars) scatter on the $D_A^2 Y_{500} - L_{500}$ relation. The coarse/fine-hatched regions corresponds to the 1 $\sigma$ uncertainties on the intrinsic scatter reported in Arnaud et al. (2010) and Planck Collaboration (2011g), respectively.
6. Robustness of the results

As in the other four Planck SZ papers (Planck Collaboration 2011d,e,g,h), we test the robustness of our results for the effect of several instrumental, modelling, and astrophysical uncertainties. Tests common to all Planck SZ papers are discussed in detail in Sect. 6 of Planck Collaboration (2011d). Of these, calibration and colour correction effects are relevant for our analysis. Calibration uncertainties are shown to propagate into very small uncertainties on SZ signal measurements (~2%) and colour correction is found to be a ~3% effect for Planck bands.

In the following we report on robustness tests aimed at completing this investigation. We show that our results are robust with respect to the instrumental uncertainties, that they are insensitive to the finest details of our cluster modelling, and that they are unaffected by radio source contamination. We show that restricting the analysis to the reference homogeneous subsample of NORAS/REFLEX clusters leads to measurements fully compatible with those we obtain for the whole sample.

6.1. Beam effects

The beam effects studied in Planck Collaboration (2011d) are further scrutinised by directly estimating their impact on our results. To this end, the whole analysis is redone by assuming different beam FWHM. For simplicity, we systematically increase/decrease the adopted beam FWHM for all channels simultaneously by adding/removing the conservative uncertainties given in Table 1 from the fiducial beam FWHM values. We find that the binned SZ signal varies by at most 2% from the value computed using the fiducial beams FWHM.

6.2. Modelling

The effects of changes in the underlying X-ray based model on our results are investigated by repeating the full analysis as for the fiducial case, but by assuming the standard slope of the $M_{500}-Y_X$ relation and/or the intrinsic $L_{500}-M_{500}$ relation (see Sect. 3). For simplicity, in the following we discuss results obtained by varying only one assumption at a time. We find that the effect resulting by varying both assumptions is equivalent to the sum of the effects obtained by varying the two assumptions separately.

As expected from the weak dependence of cluster size $R_{500}$ on luminosity, the measured SZ signal is barely affected by these changes. If the standard slope case is adopted instead of the empirical one, the bin averaged SZ signal changes by less than a few percent at all luminosities and the same is found when the intrinsic $L_{500}-M_{500}$ relation is adopted. The model predictions are of course more affected by changes in the assumed scaling relations. In Fig. 8 we contrast the Planck -to-model ratio obtained for the different cases. The figure shows that the assumption on the slope of the $M_{500}-Y_X$ relation has a fully negligible impact. On the other hand it shows that the intrinsic $L_{500}-M_{500}$ relation is not compatible with our measurements (>5σ discrepancy). This finding is not surprising given the fact that when adopting the intrinsic $L_{500}-M_{500}$ relation one assumes that selection effects of our X-ray sample are negligible. Notice that the WMAP-5 yr data used in the similar analysis by Melin et al. (2011) did not have sufficient depth to come to this conclusion. Furthermore, the agreement of our results for the rEXCESS and intrinsic $L_{500}-M_{500}$ relations at high luminosity confirms that Malmquist bias is small for very luminous objects.

6.3. Intrinsic dispersion in the $L_{500}-M_{500}$ relation

The intrinsic dispersion in the $L_{500}-M_{500}$ relation dominates the uncertainty on the clusters’ size $R_{500}$ in our analysis. We investigate how this propagates into the uncertainties on the binned SZ signal by means of a Monte Carlo (MC) analysis of 100 realisations. We use the dispersion given in Table 2 and, for each realisation, we draw a random mass log $M_{500}$ for each cluster from a Gaussian distribution with mean given by the $L_{500}-M_{500}$ relation and standard deviation $\sigma_{M_{500}}$. For each realisation, we extract the signal with the new values of $M_{500}$ (thus $R_{500}$). The standard deviation of the SZ signal for the 100 MC realisations in a given luminosity bin is found to be at most ~3% of the signal. Hence, given the size of the total errors on the binned SZ signal (see Fig. 3) our conclusions are fully unaffected by this effect.

6.4. Pressure profile

Furthermore, we investigate how the uncertainties on the assumed pressure profile propagates into the uncertainties on the binned SZ signal. For simplicity, we only quantify the largest possible effect by redoing the analysis but adopting the pressure profile parameters for the cool-core and morphologically disturbed subsamples given in Table 3, i.e. we assume that all clusters in the sample are cool-core or morphologically disturbed. Both of the two resulting sets of binned SZ signal deviate from the one derived assuming the universal pressure profile by approximatively 8% in the lowest luminosity bin and decrease linearly with increasing log $L_{500}$, becoming approximatively 1% in the highest luminosity bin. Furthermore the normalisation of Eq. (4) changes by less than 5% if the average pressure profiles...
parameters of cool-core and morphologically disturbed clusters given in Table 3 are adopted instead of the ones for the average profile, implying that our SZ signal predictions are robust. Considering the total errors and their trend with luminosity, we conclude that our findings are fully unaffected by the exact shape of the SZ template.

6.5. X-ray sample

Because of the reasons detailed in Sect. 2.2, we also repeated our analysis by considering the NORAS/REFLEX control sample and find results fully consistent with those derived for the full sample. The results are shown in terms of Planck-to-model ratio in Fig. 9. Notice that in this case the luminosity binning is chosen so as to be comparable with that in the WMAP-5 yr analysis of Melin et al. (2011). The comparison between WMAP-5 yr and Planck results is discussed in Sect. 7 below.

6.6. Radio contamination

In addition we investigated the effect of contamination by radio sources on our results. Most radio sources are expected to have a steep spectrum and hence they should not have significant fluxes at Planck frequencies. However, some sources will show up in Planck LFI and HFI channels if their radio flux is sufficiently high and/or their spectral index is near zero or positive. Extreme examples are the Virgo and Perseus clusters that host in their interior two of the brightest radio sources in the sky. In the ESZ sample (Planck Collaboration 2011d) there are also a few examples of clusters with moderate radio sources in their vicinity (1 Jy or less in NVSS) and still significant signal at LFI (and even HFI) frequencies. To check for possible contamination we combine data from SUMSS (a catalog of radio sources at 1.4 GHz, Bock et al. 1999) and NVSS (a catalog of radio sources at 0.85 GHz, Bock et al. 1999) and find results fully consistent with those derived for the full sample. Interestingly we find that, as expected, the individual SZ signal is on average lower than the X-ray based predictions in clusters that are likely to be highly contaminated. This is shown in Fig. 7 where clusters associated with radio sources with fluxes larger than 5 Jy are shown by the red symbols. However, given the very low fraction of possibly contaminated clusters, we find that bin averaged signal is fully unaffected when these are excluded from the analysis.

7. Discussion and conclusions

As part of a series of papers on Planck early results on clusters of galaxies (Planck Collaboration 2011d,e,f,g,h), we measured the SZ signal in the direction of ~1600 objects from the MCXC (Meta-Catalogue of X-ray detected Clusters of galaxies, Piffaretti et al. 2011, see Sect. 2.2) in Planck whole sky data (see Sect. 2.1) and studied the relationship between X-ray luminosity and SZ signal strength.

For each X-ray cluster in the sample the amplitude of the SZ signal is fitted by fixing the cluster position and size to the X-ray values and assuming a template derived from the universal pressure profile of Arnaud et al. (2010). The universal pressure profile was derived from high quality data from REXCESS. Recently, Sun et al. (2010) found that the universal pressure profile also yields an excellent description of systems with lower luminosities than those probed with REXCESS. This implies that the adopted SZ template is suitable for the entire luminosity range explored in our work.

The intrinsic SZ signal $D_{500}^2Y_{500}$ is averaged in X-ray luminosity bins to maximise the statistical significance. The signal is detected at high significance over the X-ray luminosity range $10^{42}$ erg s$^{-1} \lesssim L_{500}E(z)^{-7/3} \lesssim 10^{43}$ erg s$^{-1}$ (see Fig. 2).

We find excellent agreement between observations and predictions based on X-ray data, as shown in Fig. 4. Our results do not agree with the claim, based on a recent WMAP-7 yr data analysis, that X-ray data over-predict the SZ signal (Kahrik et al. 2011). Due to the large size and homogeneous nature of
the MCXC, and the exceptional internal consistency of our cluster model, we believe that our results are very robust. Moreover, as reported in Sect. 6, we show that our findings are insensitive to the details of our cluster modelling. Furthermore, we have shown that our results are robust against instrumental (calibration, colour correction, beam) and astrophysical (radio contamination) uncertainties.

Our results confirm to a higher significance the results of the analysis by Melin et al. (2011) based on WMAP-5 yr data. This is shown in Fig. 9 where the data-to-model ratio as a function of luminosity is presented. Luminosity bins are chosen so as to be comparable to those of Melin et al. (2011), and the Planck results are presented for the whole sample used in this work and also for the NORAS/REFLEX sample adopted in Melin et al. (2011). In addition to the good agreement between results from the two data sets, the figure shows that in the WMAP-5 yr study by Melin et al. (2011) statistical uncertainties are dominant. As shown in Sect. 4.2, Planck data allows us to overcome this limitation and to investigate the intrinsic scatter in the scaling relation between intrinsic SZ signal $D_A^2 Y_{500}$ and X-ray luminosity $L_{500}$ (see Sect. 5.3). We find a $\sim 40\%$ intrinsic scatter in the $D_A^2 Y_{500} - L_{500}$ relation and show that it is linked to cluster dynamical state.

The agreement between luminosity binned X-ray predictions and Planck measurements is reflected in the excellent accord between predicted scaling relation and best fitting power law model to the $D_A^2 Y_{500} - L_{500}$ relation. The power law fit, which is performed on individual data points, is compared by Planck Collaboration (2011g) to the calibration derived from a sample of galaxy clusters detected at high signal to noise in the Planck survey (the ESZ sample, see Planck Collaboration 2011d) and with high quality X-ray data from XMM-Newton. As discussed in Planck Collaboration (2011g) the slight differences between the two best fitting relations reflect the difference between the selection of the adopted samples. Indeed, the X-ray sample used in the present work is X-ray selected and therefore biased towards the cool core systems, while the sample used in Planck Collaboration (2011g) is SZ selected.

As mentioned in Sect. 4.2, the luminosity range where we are not able to detect the SZ signal because of the small number of low mass objects (see Fig. 2), is explored in Planck Collaboration (2011h). In the latter analysis we use the optical catalogue of $\sim 14,000$ MaxBCG clusters (Koester et al. 2007) and, in a fully similar way as done in this work, extract the optical richness binned SZ signal from Planck data. By combining these results with the X-ray luminosity of the MaxBCG clusters measured by Rykoff et al. (2008) by stacking RASS data, in Planck Collaboration (2011h) we derive the $D_A^2 Y_{500} - L_{500}$ relation for the MaxBCG sample. This result is shown together as reported in Sect. 6, we show that our findings are insensitive to the details of our cluster modelling. Furthermore, we have shown that our results are robust against instrumental (calibration, colour correction, beam) and astrophysical (radio contamination) uncertainties.

Planck Collaboration 2011e, and discussion therein), improved understanding of the evolution of SZ-X-ray scaling relations is clearly desired. High quality data similar to those used in Planck Collaboration (2011g), but for higher redshift clusters will provide tight constraints on evolution, in particular when newly SZ discovered clusters (see Planck Collaboration 2011d, and references therein) with high quality X-ray and optical data are included.

Acknowledgements. This research has made use of the X-Rays Clusters Database (BAX) which is operated by the Laboratoire d’Astrophysique de Turbe-Fouloulouze (LATT), under contract with the Centre National d’Études Spatiales (CNES). We acknowledge the use of the HEALPix package (Górski et al. 2005). Fig. 10. Bottom panel: comparison between our results (red diamonds, as in left-hand panel Fig. 4) and those obtained by Planck Collaboration (2011h) (green triangles), where MaxBCG clusters are investigated. X-ray luminosities and associated error bars for the MaxBCG clusters are based on the analysis of Rykoff et al. (2008). Vertical error bars are as in Fig. 4 and the X-ray prediction (i.e., Eq. (6)) is shown by the dashed blue line. Top panel: X-ray luminosity histograms of the MCXC (red) and MaxBCG (green) samples. For the MCXC the width of the bars is equal to the luminosity bin width, while for the MaxBCG we adopt the horizontal error bar shown in the bottom panel.
